A reinforcement sensitivity theory explanation of antisocial behaviour

Alison M. Bacon, Philip J. Corr, Liam Paul Satchell

A comprehensive explanation of antisocial behaviour (ASB) needs to focus on both individual differences in personality and life events as potentially predisposing factors. The current studies investigated the relative influence of both of these in males and females. We used the Reinforcement Sensitivity Theory (RST) of personality to investigate the extent to which dispositional approach and avoidance tendencies relate to ASB. In the first study, 287 participants reported their engagement in ASB and completed the RST Personality Questionnaire (RST-PQ). In the second study, a new sample of 282 participants completed the same measures as well as reporting the extent to which they had experienced life strains. Results from both studies showed a positive association between goal-drive persistence and ASB in males; while in females, a positive association was found between impulsivity and ASB. In Study 2, life strains explained further variance in ASB and this also showed a gender differentiation: in males, there was a stronger relationship between financial strains and ASB while females showed an association between relational strains and ASB. Overall, results suggested that ASB is more pronounced in the male sample with an instrumental purpose while in the female sample personal life events are of more relevance.
reactivity” and “impulsivity” which are concerned with processes closer to the final reinforcer (Corr & Cooper, 2016). Activation of the BAS is said to lead to the experience of hopeful excitement, drive persistence to reach desired goals, and elation when they have been attained (Corr et al., 2013).

A second system, the Fight-Flight-Freeze System (FFFS), mediates reactions to all aversive stimuli (conditioned or otherwise), leading to avoidance and escape behaviours. A third system, the behavioural inhibition system (BIS), is specifically sensitive to goal-conflict (e.g., equal activation of the FFFS and BAS - or, indeed, goal conflict of any kind with sufficient motivational intensity) and it motivates passive avoidance behaviour. As such, the BIS is responsible for detecting and resolving conflict, rather than simply being sensitive to punishing stimuli, and contributes to risk assessment and potentially to rumination, which can result in the experience of anxiety. This RST structure is now widely recognized, in conceptual and psychometrical terms (Corr, 2011; Gray & McNaughton, 2000; Perkins, Kemp, & Corr, 2007; for review, see Corr, 2016; Corr & Cooper, 2016).

The RST of personality is of interest to ASB given the extant evidence. For example, impulsivity has consistently been implicated in adolescent ASB (Maneiro, Gómez-Fraguera, Cutrin, & Romero, 2016) as has the related construct of sensation seeking – that is, the tendency to desire and actively seek out novel and intensely stimulating experiences and the willingness to take risks for the sake of these ‘thrills’ (Zuckerman, 1994). A large body of research has suggested that high levels of sensation seeking may be a risk factor for criminal and antisocial behaviours in student, community and convicted samples (Gomá-i-Freixanet, 1995; Hansen & Breivik, 2001; Horvath & Zuckerman, 1993; Pleiferbaum & Wood, 1994; Zuckerman, 2007). In line with the age-related prevalence of ASB, sensation seeking tends to peak in adolescence (Zuckerman, 2007). Other personality traits that have been associated with ASB include lower than average levels of social competence (Palmer & Hollin, 1999), lack of empathy (Cohen & Strayer, 1996; Jolliffe & Farrington, 2007) and impaired emotional and physical self-regulation (Eisenberg et al., 1996; Gottfredson & Hirschi, 1990; Moffitt et al., 2011). Accordingly, antisocial individuals have been shown to score less highly on measures of related constructs such as cognitive ability (Brackett, Mayer, & Warner, 2004) and trait-emotional intelligence (Bacon, Burak, & Rann, 2014), though the latter finding was found only for a male sample (no such finding was present in the female sample).

Little research to date has explored the contribution of RST personality factors to ASB. In one study, Morgan, Bowen, Moore, and van Goozen (2014) indicated heightened BAS and lowered BIS in a sample of male antisocial adolescents, as compared with a non-offending sample. These findings present a useful insight into motivational drive towards ASB. However, Morgan et al. used an RST questionnaire measure (Carver & White, 1994) which assesses personality factors on the basis of the original conceptualisation of the theory (Gray, 1982) – specifically, they measured BIS and BAS as unitary concepts and did not include a measure of the FFFS. As such, their results did not take into account the most recent developments in RST (Corr, 2016; Corr & Cooper, 2016).

In the present two studies, we employed a contemporary and more comprehensive psychometric approach that differentiates FFFS and BIS, as well as providing a more nuanced conceptualisation and measurement of the BAS (Corr & Cooper, 2016). In addition, Morgan et al.’s (2014) study comprised only male participants - males typically report higher levels of ASB than females especially for more criminal and violent activities, although the gender gap narrows when minor offences are taken into account. It is also known that, as a group, males score more highly on measures of sensation seeking (Zuckerman, 1994, 2007). In the present research, we explored possible gender differences in the relationships between ASB and an expanded theoretical and psychometrical definition of RST personality factors.

1. Study 1

In Study 1, our aim was to examine the relationship between ASB in adolescence and emerging adulthood and personality traits assessed within the revised RST framework. In line with what is known about personality and ASB, we predicted a positive association between levels of ASB and impulsivity for both males and females. Given Morgan et al.’s (2014) study, we also expected to observe a positive association between ASB and BAS traits and a negative association with BIS.

1.1. Method

1.1.1. Participants

Two hundred and eighty-seven undergraduates participated in return for course credit: 169 females ($M_{age} = 20.66, SD = 2.44$) and 118 males ($M_{age} = 20.29, SD = 2.12, p = 0.21, d = 0.16$).

1.1.2. Materials and procedures

1.1.2.1. Antisocial behaviour. We presented a list of 35 behaviours and participants were asked to respond yes to any they had engaged in since the age of 12 years. Items ranged across non-illegal but undesirable behaviours, such as cheating in an exam, interpersonal behaviours such as bullying, relatively minor criminal offences such as using public transport without a ticket to more serious offences such as assault. This method has been used in previous published research on ASB (Bacon et al., 2014; Bacon, Lenton-Maughan & May, 2018). Scores were obtained by summing the yes responses to provide an overall ASB score which presented good reliability ($\alpha = 0.88$).

1.1.2.2. Reinforcement Sensitivity Theory of Personality Questionnaire (RST-PQ, Corr & Cooper, 2016). This 65-item scale measures three major systems: Fight-Flight-Fear System (FFFS; e.g., “I am the sort of person who easily freezes-up when scared”); Behavioural Inhibition System (BIS; e.g., “When trying to make a decision, I find myself constantly chewing it over”); and four Behavioural Approach System (BAS) factors: Reward Interest (e.g., “I regularly try new activities just to see if I enjoy them”), Goal-Drive Persistence (e.g., “I am very persistent in achieving my goals”), Reward Reactivity (e.g., “I get a special thrill when I am praised for something I've done well”), and impulsivity (e.g., “I find myself doing things on the spur of the moment”). Participants respond on a scale from 1 (not at all) to 5 (highly). The RST-PQ scales presented good internal reliability with the present sample: FFFS = 0.79; BIS = 0.94; BAS reward interest = 0.79; BAS goal-drive persistence = 0.87; BAS reward reactivity = 0.81; BAS impulsivity = 0.70.

1.1.2.3. Social Economic Status (SES). We collected family background SES as a control measure. Participants were shown a list of six demographic classifications used in the UK for market research purposes (Market Research Society, 2016). The SES levels were coded from 1 (long-term unemployed, for whatever reason) to 6 (professional occupations). Participants were asked to indicate which best reflected the home where they grew up and as such, higher score suggested a higher family SES.

Ethical approval was obtained from the university faculty ethics committee. All participants completed the following measures presented online via the Survey Monkey platform.

1.2. Analysis

Analysis was conducted using SPSS version 22. Gender differences in ASB were calculated by an independent samples t-test and in the RST factors by a multivariate analysis of variance (MANOVA). Associations between variables were examined using Pearson’s product moment correlations (two-tailed). Linear multiple regression was used to examine the extent to which the RST factors could account for variance in
ASB. For each RST factor score, values for skewness and kurtosis fell well within the acceptable range of between −2 and +2 suggesting the data were close to normally distributed (West, Finch, & Curran, 1995). ASB scores showed negatively skewed distributions as participants tended to report fairly low levels (as we might expect with a non-forensic population). However, on calculating the regressions residuals, scores were found to be normally distributed suggesting the assumptions unpinning regression were not violated.

1.3. Results

Table 1 presents descriptive statistics for the male and female samples. The reported SES for the male (M = 3.82, SD = 1.86) and female (M = 3.94, SD = 1.76) samples did not significantly differ (p = 0.42, d = 0.07).

We found a higher level of ASB in the male sample: t (285) = 2.94, p = 0.003, d = 0.35. A Multivariate analysis of variance (MANOVA) on the RST factors indicated significant effects of gender on goal-drive persistence F (1, 285) = 17.72, p < 0.001, η² = 0.06, reward reactivity F (285) = 22.49, p < 0.001, η² = 0.07, and FFFS F (285) = 15.19, p < 0.001, η² = 0.05, with higher scores in the female sample. Males however score more highly than females on impulsivity F (285) = 4.36, p = 0.03, η² = 0.02 and Table 2 presents partial correlations between these measures, controlling for SES. The largest correlation between RST-PQ factors and Antisocial Behaviour (ASB) was found for BAS-impulsiveness. This fits with previous research suggesting that spontaneity and poor planning contributes to antisocial conduct. For the male sample, there were positive correlations between ASB and reward interest, goal-drive persistence and the BIS; in contrast, in the female sample, we found a negative association between ASB and goal-drive persistence only.

As Table 2 shows, using Fishers’ Z for testing the difference between two correlation coefficients, we find significant differences between the genders in BAS-goal-drive persistence and reward reactivity. For the female sample, low goal-drive persistent behaviour was associated with more ASB, but the opposite was found in the male sample where a negative correlation was observed. It is also noteworthy that in the male sample, we found little evidence of a correlation a between short-term reward reactivity and ASB, while for the female sample a significant positive association was observed. These results suggest that, for female participants, ASB is associated with impulsivity and poor long-term planning, whereas for male participants, ASB is related to reward-focussed strategic behaviour.

We conducted a linear regression analysis on ASB for the male and female samples separately, with SES and each of the RST variables entered as potential predictors. The results are shown in Table 3. For the female sample, the model accounted for 28% variance in ASB, with goal-drive persistence (negative) and reward reactivity (positive) sharing independent variance with ASB. For the male sample, the model accounted for 27% variance in ASB: for these participants, reward reactivity was also a positive factor, but in contrast to the female sample, goal-drive persistence shared positive variance with ASB.

1.4. Study 1 discussion

Study 1 revealed a key difference in male and female samples relating to the RST BAS subfactor of goal-drive persistence. For the female sample, we found a negative association between this variable and levels of ASB, while for the male sample the association was positive: the latter result supports Morgan et al. (2014), who similarly observed heightened BAS sensitivity in male participants (they did not include females in their sample). On the basis of these findings, we suggest that this reflects a tendency among high goal-drive persistent males to use ASB (and possibly crime more generally) as a means to pursue their long-term social and personal goals in an attempt to improve their social and personal circumstances. In Study 2, we extend this work to examine the possibility of the relevance of Strain Theory (Agnew, 2006, 2012).

2. Study 2

Strain theory suggests that individuals commit offences because they experience adverse life circumstances that lead to emotional and practical strains. In consequence, The goal is to escape, or cope better with, these circumstances and these goals are pursued through antisocial, rather than prosocial means. Sometimes the ASB is clearly practical, such as being short of money and stealing something to eat. In other cases, behaviours may alleviate negative emotions, possibly by using drugs or bullying. Criminal coping also occurs when people perceive that they lack the ability to deal with life situation in any other way, for instance, not having the verbal or emotional intelligence skills to deal with difficult relationships, or where violence is perceived to be an appropriate response to interpersonal conflict (Piquero, Brane, & Lynam, 2004). According to Strain Theory, the adolescent peak in ASB results from restricted life opportunities and choices: typically, young people have little say in terms of where they live, who with, the school they attend, etc. If these settings are distressing or abusive, there is little they can do and may turn to antisocial behaviours, such as truancy, fighting back, running away etc. in order to escape or gain a sense of control (Agnew, 1985, 2006, 2012).

Many studies which have attempted to explain adolescent ASB have suggested that social factors play a large part in its aetiology, particularly the role of parenting and disruptive family environments (Johnson, Smailes, Cohen, Kasen, & Brook, 2004) and factors associated with low socio-economic status, such as poverty, low educational attainment, inequality and social exclusion. For instance, Kramer (2000) argued that structural forces reduce the ability of families and communities to provide the social support and informal social control needed to prevent ASB in young people. However, it has also been
argued that ASB is not caused by low SES per se, but rather the economic problems associated with it (Agnew, Matthews, Bucher, Welcher, & Keyes, 2008). It is also important to note evidence that ASB is a manifestation of an interaction between innate traits and social circumstances (Tuvblad, Grann, Sarnecki, & Lichtenstein, 2005) - for example, the effects of impulsivity are stronger in poorer neighborhoods (Lynam et al., 2000).

In Study 2, we examine the relationship between ASB, RST traits and three types of strain known to precipitate ASB and crime (Agnew, 2006). Typically, if males who experience a lot of life strain when younger are those most likely to pursue goals though antisocial means, then we would expect to observe the same positive association between BAS goal-drive persistence and ASB as found in Study 1; however. We then would expect to observe the same positive association between BAS goal-drive persistence and ASB as found in Study 1; however. We expect this association to be moderated: the association should be strengthened in the male sample who have experienced the most strain.

For our female sample, the results of Study 1 suggest that, as ASB is not goal-oriented, those with least BAS goal-driven persistence should influence of strains, with males typically experiencing more of those which are thought to be especially conducive to crime, such as hard discipline, poor school achievement, abusive and aggressive peers criminal victimisation and homelessness (Broidy & Agnew, 1997; Hay, 2003); in contrast, females typically report more gender-focussed strains, such as sexual assault and intimate partner violence. While some studies have found that males typically are most likely to cope by the use of crime, other studies have suggested that girls typically living in an environment of familial and relational discord often respond antisocially, and that females typically generally tend to be more sensitive than males to strains in close relationships (Hay, 2003; Hoffman & Su, 1997).

In Study 2, we examined three types of strain: financial, relational and familial. Based on the results of Study 1, we predicted that in the male sample would be found most influence of financial and relational strains, with males who are higher in goal-drive persistence and have experienced these strains reporting higher levels of ASB. In contrast, in the female sample, we expected to observe higher reports of ASB among participants who had experienced familial strain, though given the results of Study 1, this link may not necessarily be associated with goal-drive persistence.

Recent research has shown that participants recruited from the site are psychologically naive and diverse in terms of representations of the general population (Peer, Brandimarte, Samat, & Acquisti, 2017).

### 2.1. Method

#### 2.1.1. Participants

Study 2 extended the research to a non-student sample. Two hundred and eighty two participants were recruited from Prolific Academic, an online research platform, 166 females (Mage = 35.19, SD = 11.87) and 116 males (Mage = 35.26, SD = 12.74, p = 0.96). No significant gender differences in reports of background SES were observed (Males M = 4.76, SD = 1.60; Females M = 4.91, SD = 1.42; p = 0.41, d = 0.09). Table 4 presents the descriptive statistics for the other measures. Again, in the male sample we found reports of significantly more ASB than the female sample, t(480) = 4.07, p < 0.001.

MANOVA on the RST factors indicated significant effects of gender on reward interest where males score most highly, F (1, 280) = 6.25,
males and females reported similar levels of each type of strain, family females are the higher scorers. In terms of the three types of strain, \( \eta^2 = 0.03 \), and FFFS \( F(280) = 22.09 \), with Study1, significance differences were found in the relationship between ASB and both goal-drive persistence and reward reactivity: the male sample showed positive associations, while the female sample showed negative associations for goal-drive persistence and, negligible, for reward reactivity. Females who reported higher levels of antisocial behaviour are impulsive, meaning differences in the type of strain, males and females reported similar levels of each type of strain, family \( p = 0.56 \), financial \( p = 0.15 \) and abuse \( p = 0.18 \).

Table 5 presents correlations for Study 2. Again, BAS impulsivity was positively correlated with ASB for both gender groups and, in line with Study1, significant gender differences were found in the relationship between ASB and both goal-drive persistence and reward reactivity: the male sample showed positive associations, while the female sample showed negative associations for goal-drive persistence and, negligible, for reward reactivity.

In addition, Study 2 presented gender-differences in the relationship between ASB and reward interest, with males showing a positive association and females a negative one. Female ASB was also positively associated with BIS in this study. A similar relationship was observed in Study 1, but in that case, the association did not reach statistical significance. All three of the strains showed significant positive associations with ASB in the female sample (family \( r = 0.29 \) financial \( r = 0.41 \), relational \( r = 0.59 \), \( p < 0.001 \), in each case); in contrast, in the male sample, this was also the case for family (\( r = 0.37 \)) and financial strains (\( r = 0.35 \), \( p < 0.001 \), in both cases) -however, relational strain showed only a negligible relationship with ASB for males (\( r = -0.02 \)).

We computed a linear regression that comprised the RST and strain factors as potential predictors of ASB. We conducted this analysis separately for the male and female samples and then compared the size of the influences between models using z tests for regressions (see Kleinbaum & Kupper, 1978; Wuensch, 2016). As shown in Table 6, in both models, strain criteria were the strongest predictors of ASB, however, for the female sample, this was found only for relational strain while in the male sample, this was found only for financial strain. Notably, significant differences between the models were found, again, in the negative goal-drive persistence variable for the female sample and the positive goal-drive persistence for the male sample. Furthermore, the predictive value of relational strain was significantly different between the male and female samples; a weak negative correlation for the male one and a strong positive correlation for the female one. Overall, the female sample model accounted for 46% variance in ASB, while the male sample model shared 31% variance with ASB.

We also tested potential interaction variables to investigate the predicted moderation effects of strain on the goal-drive persistence-ASB and reward reactivity-ASB relationships. However, none of these showed independent predictive power or improved the fit of the models significantly (\( p > 0.5 \) in all cases).

Overall, this second study replicated and extended the associations found in Study 1. Again, all participants showed a positive relationship between ASB and impulsivity and results further strengthened the claim that higher goal-drive persistence increases ASB in the male sample but and deters it in the female sample. In addition, Study 2 revealed that life strains has a greater impact on propensity to ASB than RST personality traits. Particularly, it was found that financial strains strongly related to ASB in the male sample while it was relational strains that appeared important in the female sample.

3. General discussion

Overall, these two studies present a coherent empirical picture. They show that personality traits measured within the revised RST framework influence levels of adolescents ASB and that there are meaningful differences in the gender samples. Study 1 showed that males who reported higher levels of antisocial behaviour are impulsive, as previous research has shown, and also present with higher goal-drive persistence and reward reactivity. Females reporting antisocial behaviour are also impulsive, but in contrast to males show no evidence of goal or reward-oriented behaviour.

Study 2 examined whether goal-orientation behaviour could be related to strain, for instance whether ASB might be a way to escape or fight back against deprivation, inequality or perceived injustice. We replicated the associations of goal-drive persistence in a non-student population, though in this case the regression analysis suggested that BAS response reactivity was additionally influential for females as well as males. As expected, we showed that strains relating to family, financial and relational situations impact on level of ASB overall but, additionally, evidence of gender differences in the type of strain which is most predictive. Financial strains seem a significant factor for both groups, while relational factors seemed additionally important for females only. In sum, individuals who experience strains in childhood and adolescence are more likely to engage in ASB, and so are individuals who are impulsive, responsive to potential rewards and, in the case of males, goal-driven and persistent in their BAS-related behaviour. However, of theoretical significance, and contrary to prediction, these strain and personality factors do not appear to interact. In other words, RST related traits and strains predict antisocial behaviour independently.

The observed differences between male and female samples in terms of their relationship between goal-drive persistence and ASB may be associated with characterisations of antisocial behaviour as either instrumental (i.e., proactive, purposeful and goal directed) or reactive (defensive, expressive and often hostile). These classifications have been widely applied to specifically aggressive behaviours (Berkowitz, 1993; Kempes, Matthys, de Vries, & van Engeland, 2005) and to adult criminality (Piquero & Tibbetts, 2002), and more recently have been extended to antisocial activities in adolescence such as theft, cheating and illicit drug use (Fontaine, 2006; Fontaine & Dodge, 2006).

In the present studies, the fact that typical male ASB is consistently related to a positive association with goal-drive persistence does
suggest that this behaviour is instrumental in nature, whereas typical female ASB seems more reactive, relating only to high impulsivity as well as to the BAS. Reactive ASB has been characterized as emotional, highly aroused, and responsive to a perceived provocation or threat (Fontaine, 2006) and BAS is responsive to aversive stimuli and motivates avoidance behaviours. As such, both forms of behaviour can be related to strain risk factors with males and females coping in different ways.

Much research has suggested gender differences in adolescent antisocial behaviour and its associated psychopathology in response to stressful circumstances. Young females predominate in relation to internalised disorders, such as depression and anxiety, while male predominates in relation to externalised, often antisocial, behaviours (Hartung, Milich, Lynam, & Martin, 2002; Huselid & Cooper, 1992; Leadbeater, Blatt, & Quinlan, 1995). Group level differences between males and females are also found in the level and nature of ASB, with males typically tending to engage in more criminal and violent activities than is typically found with females, although this gender gap narrows with minor offences. Indirect aggression (such as bullying) is prevalent among adolescent females (Archer, 2004; Osterman et al., 1998) and much of their ASB is linked to adversarial social relationships (Odgers & Moretti, 2002). Kennedy et al. (2015) report that young female offenders present with higher incidences of childhood abuse and family conflict than non-offenders. That relational strains were predictive of ASB for females, but not males, in our Study 2 may very well reflect this finding and it may be that ASB is a reaction to these factors. In contrast, for males, financial risk factors may be a more important predictor of ASB and if their goals are to overcome these circumstances, theft or other actions to obtain financial relief may clearly be instrumental in nature.

It is perhaps surprising that we did not observe the moderating effect of strain on the relationship between personality and ASB, as we predicted. One explanation may lie in the nature of our sample. Although UK student populations are increasingly heterogeneous in nature, and populations recruited through online platforms are claimed to be socially inclusive (Peer et al., 2017), it remains that individuals from the lower SES levels were underrepresented in our samples. Although participants did report ASB and the experience of strains, it may still be the case that they had protective factors (such as social support, good schooling) which, to an extent, buffered them from the negative effects. Social representativeness in participant samples has been a limitation of much research on the aetiology of ASB (Agnew et al., 2008) and emphasises how some more hard to reach sectors of society are unlikely to spontaneously engage in research.

In addition, we collected self-reports of ASB and delinquency and although such research methods are frequently employed, the limitations inherent in self-report must be acknowledged in that definitive conclusion about causality cannot be drawn (Lilienfeld et al., 2015). Furthermore, as we obtained retrospective reports of adolescent behaviour, some of these may have been subject to distortions related to memory or impression management. Personality traits (including those associated with RST) are thought to be relatively stable constructs, however, the need for longitudinal research to support the present findings, and to further understand how personality traits might relate to ASB and offending further into the life course.

In conclusion, the studies presented in this paper highlight how antisocial behaviour can result from life strains and dispositional motivational personality traits. Evidence for the influence of strains is well-established (Agnew, 2006, 2012 for reviews) but with the present results, a more complex picture is emerging whereby not only adverse life circumstances but also inherent approach and avoidance motivational tendencies are associated with ASB. Clearly, personality influences on ASB extend more widely than socio-emotional characteristics such as empathy and understanding, which have been the focus of much research. Traits such as goal-drive persistence and reward-reactivity are inherently motivational and offer a new way to understand more about how life strains can drive some individuals towards antisocial and criminal behaviour. Possibly the most important finding is that these effects appear to differ between male and female samples. Typically speaking, male ASB appears to be linked to ‘means to an end’ thinking, financial strains and personality traits associated with asissiduousness and persistence. The relational strains and impulsivity traits associated with female ASB reflects a more interpersonal-reactive pattern of behaviour. Public programmes and research need to account for the diverse criminogenic needs and motives of male and female offenders (Cauffman, 2008). Any truly comprehensive theory or intervention should account for such gender differences.
